Hermaphroditism

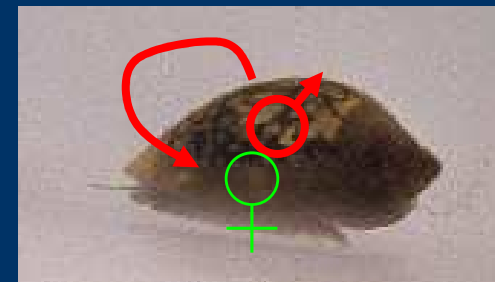

Pulmonate reproductive anatomy

A variety of possible mating systems

Outcrossing

Selfing

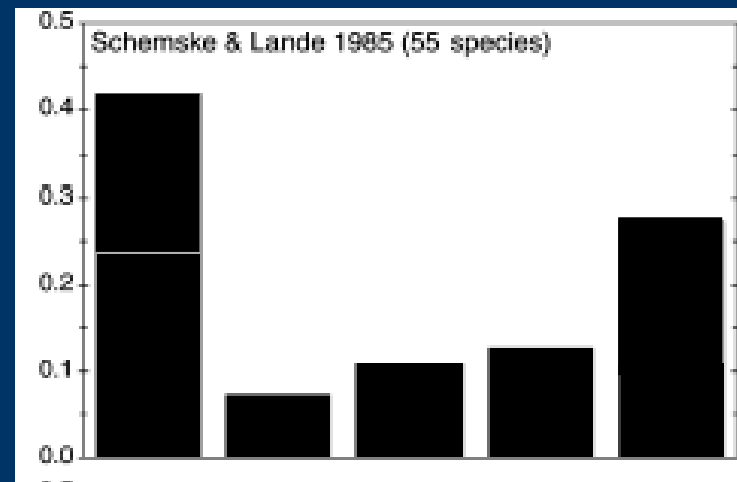

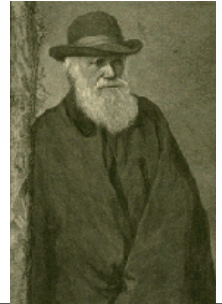

Mating strategies are diverse

- Darwin : Plants evolve specific strategies to control selfing rates : eg self-incompatibility, anther-stigma distance, etc
- Inbreeding depression is a major selective force against selfing

The Effects of Cross & Self-Fertilisation in the Vegetable Kingdom

Charles Darwin

selfing rate s

inb.
depression
 δ

Hermaphroditic animals have been less well studied

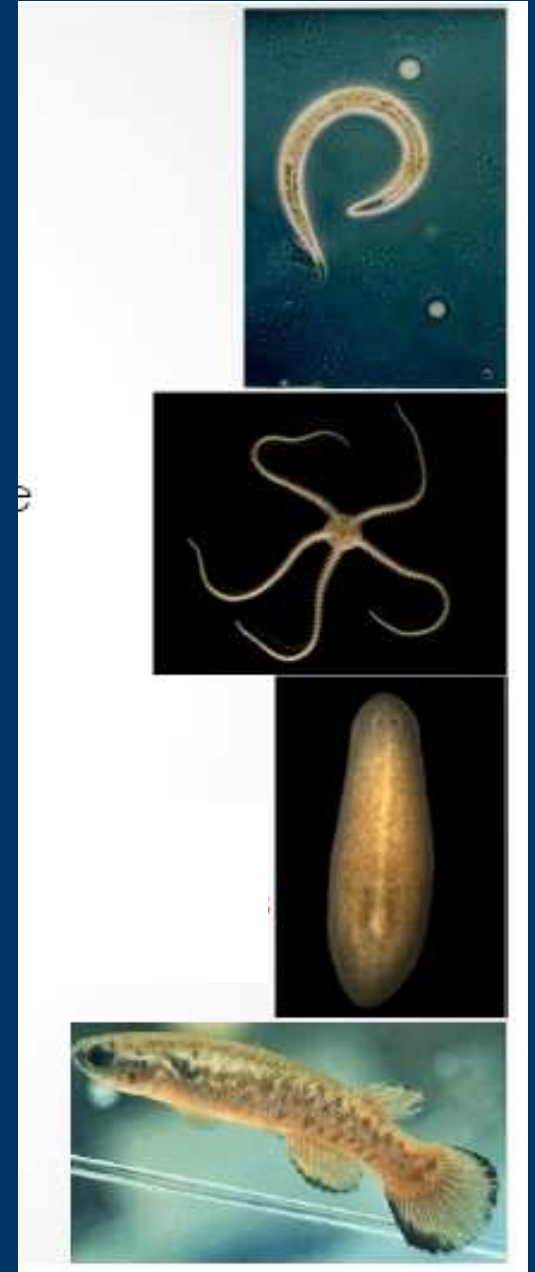

Yet they are in fact very common

Freshwater snails (Pulmonates)
= good model systems

Physa acuta

Bulinus truncatus

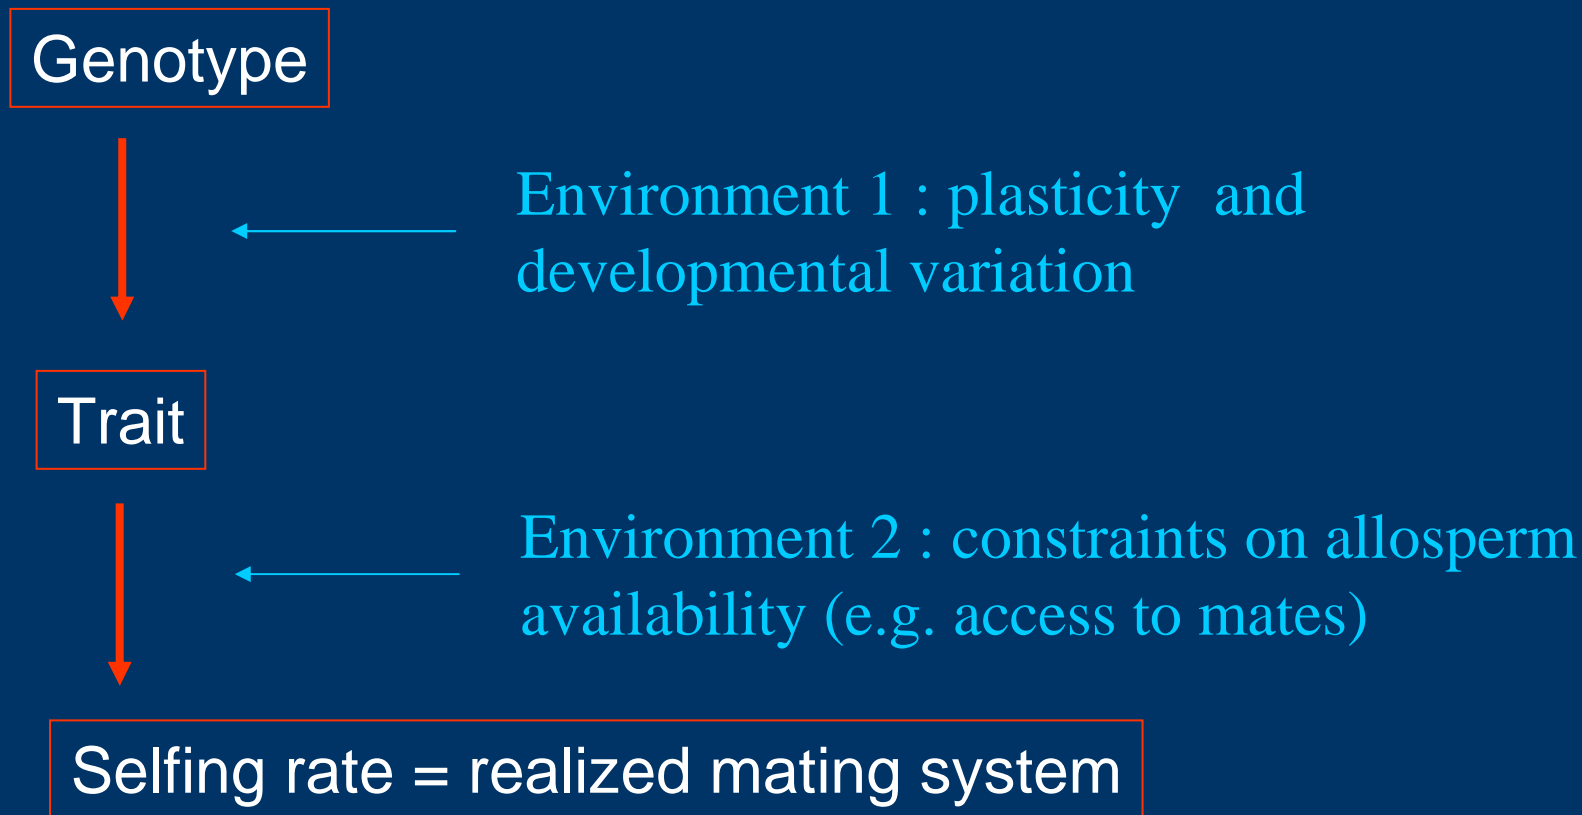

Empirical issues

- Is there variation in reproductive systems in these species ?
- To what extent can animals control their selfing rate and through what traits ? Are these traits genetically variable and can they evolve ?

Selfing rates : two layers of environment, one layer of genetics

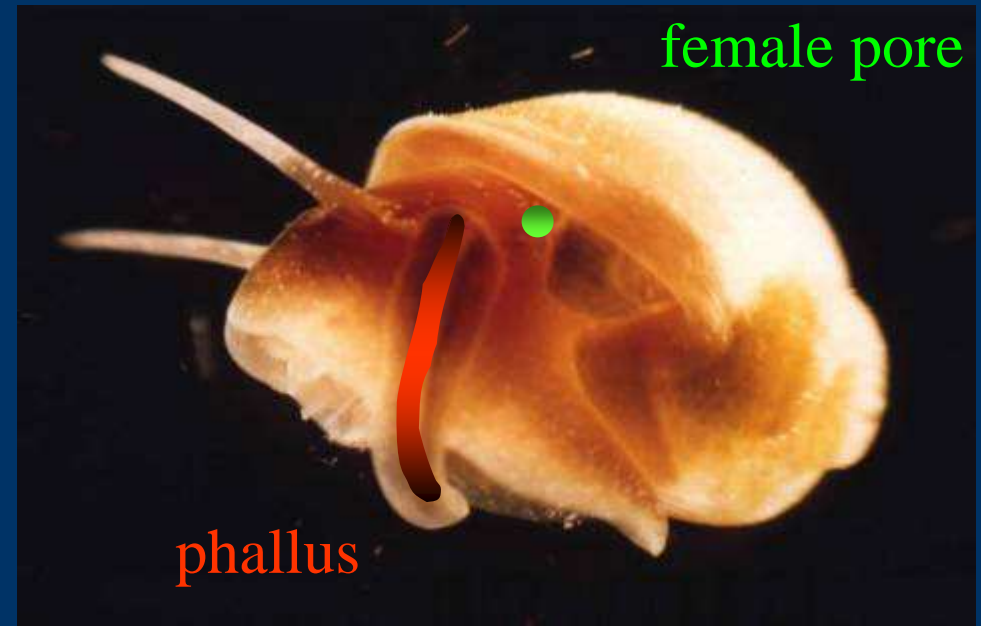

Bulinus truncatus

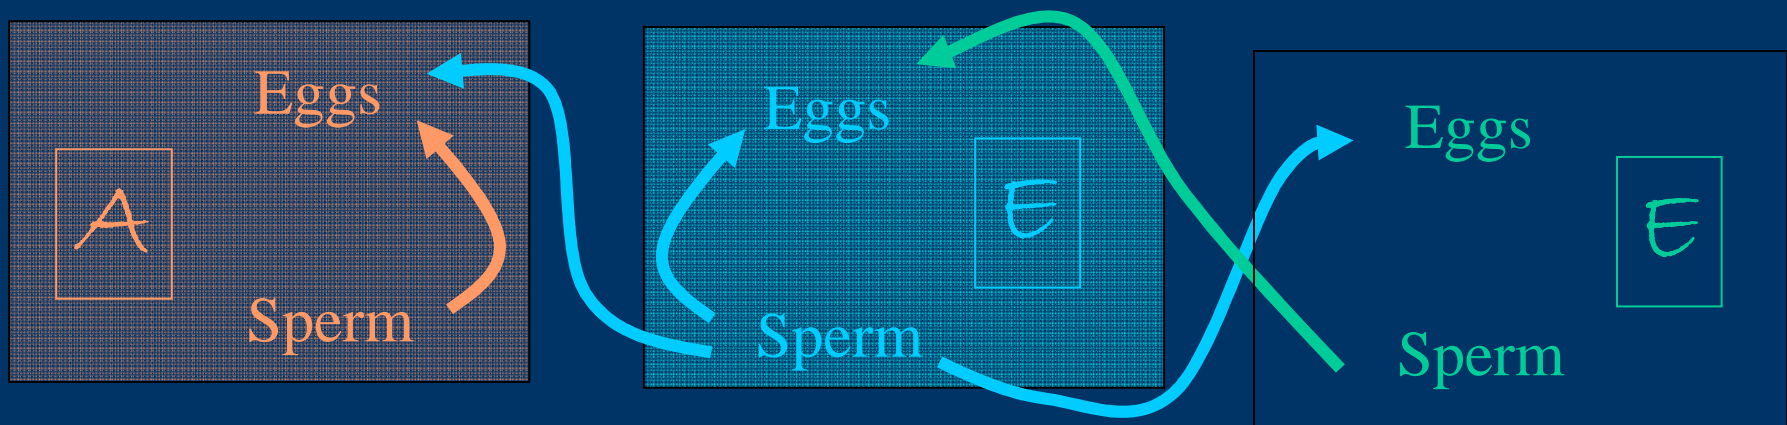

Preferential selfer

Two hermaphroditic morphs

- \mathcal{E} uphallics (regular)
- \mathcal{A} phallics (without phallus)

Both morphs can self and cross-fertilize; allosperm comes only from \mathcal{E}

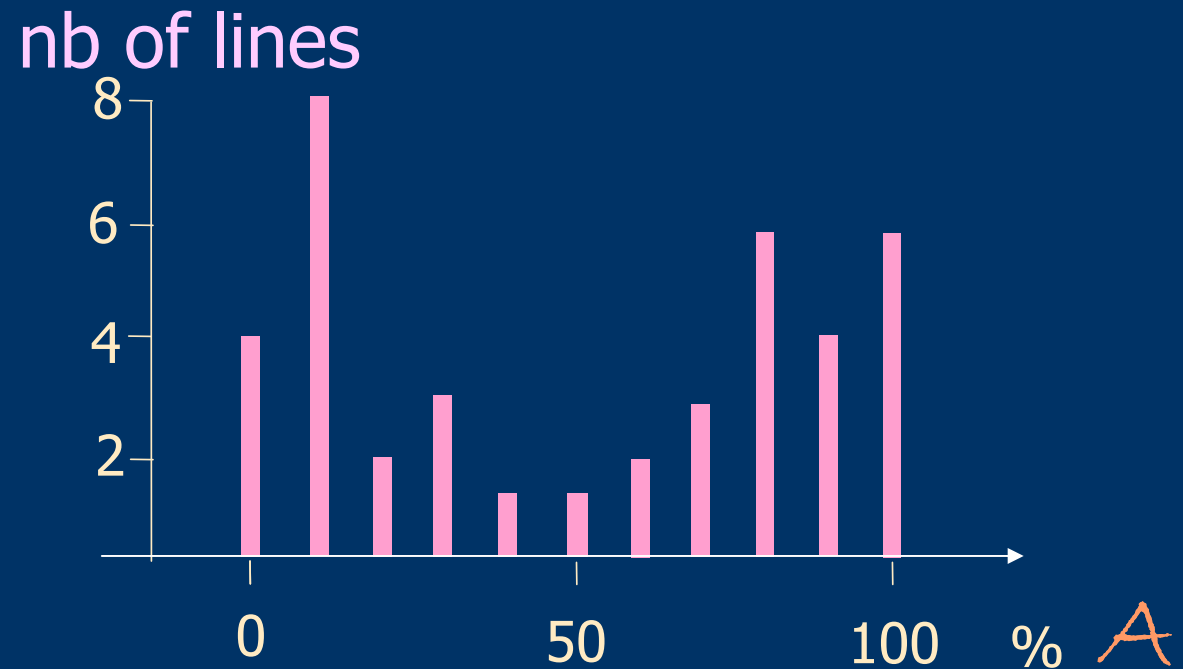

Quantitative genetic variation of aphally

- Is the inheritance of aphally Mendelian ?
- 40 Inbred lines (>14 gen enforced selfing) from 4 pops in Niger

VE : two genetically identical ind can have different morphs

Threshold trait : lines differ in their %A but all values are possible in [0,100]

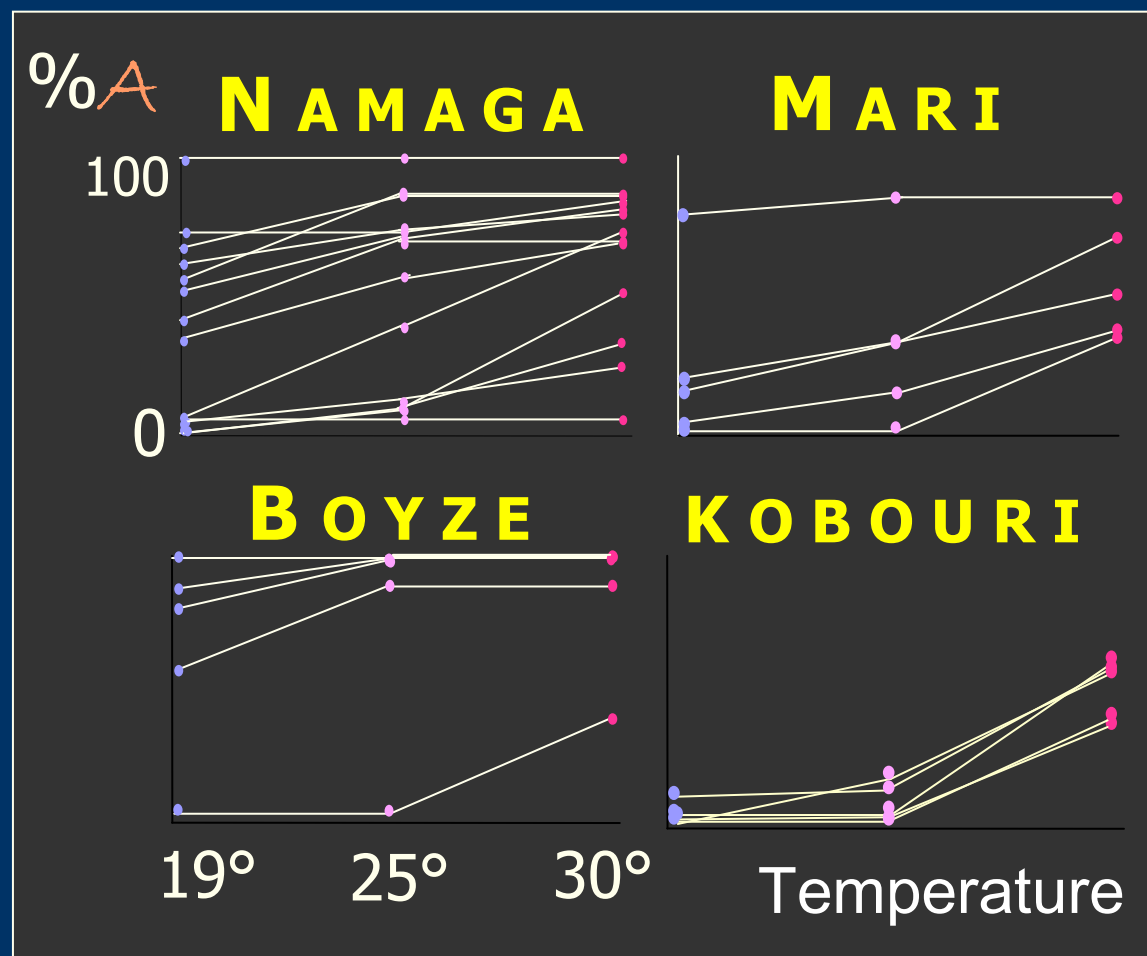

Lots of variation within most pops

Pop	H ²
Namaga	0,6
Mari	0,8
Boyze	0,5
Kobouri	0

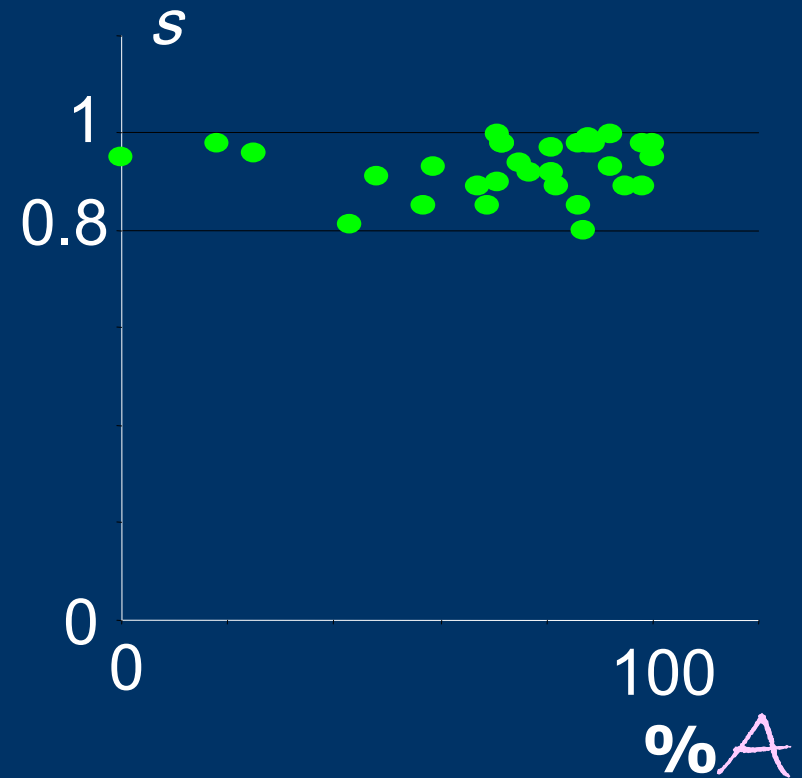

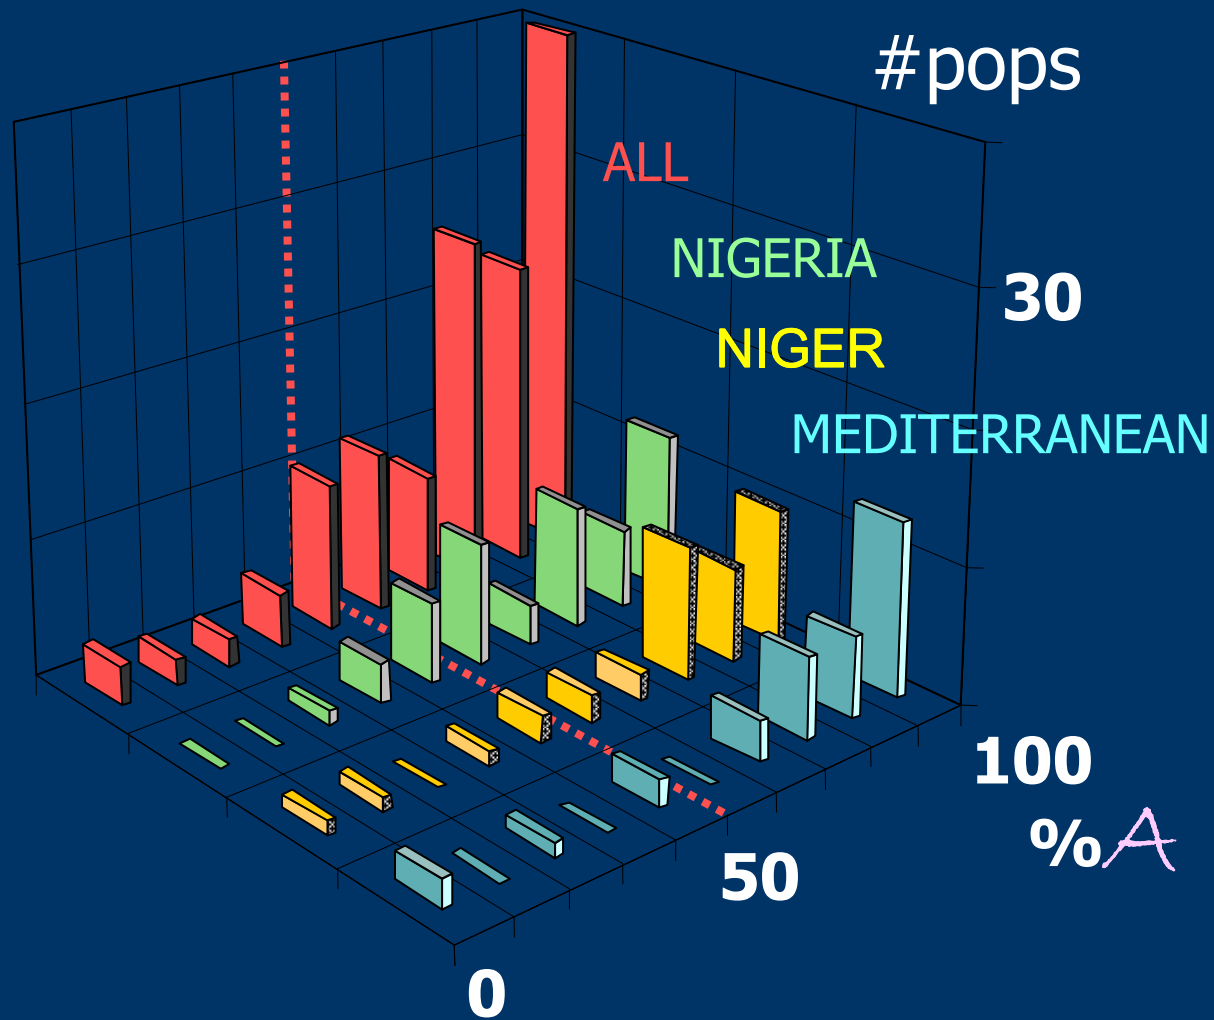

Thermal responses of aphally

Plasticity : The % A increases with temperature

Variation in reaction norms among lines :

How is aphally related to the selfing rate ?

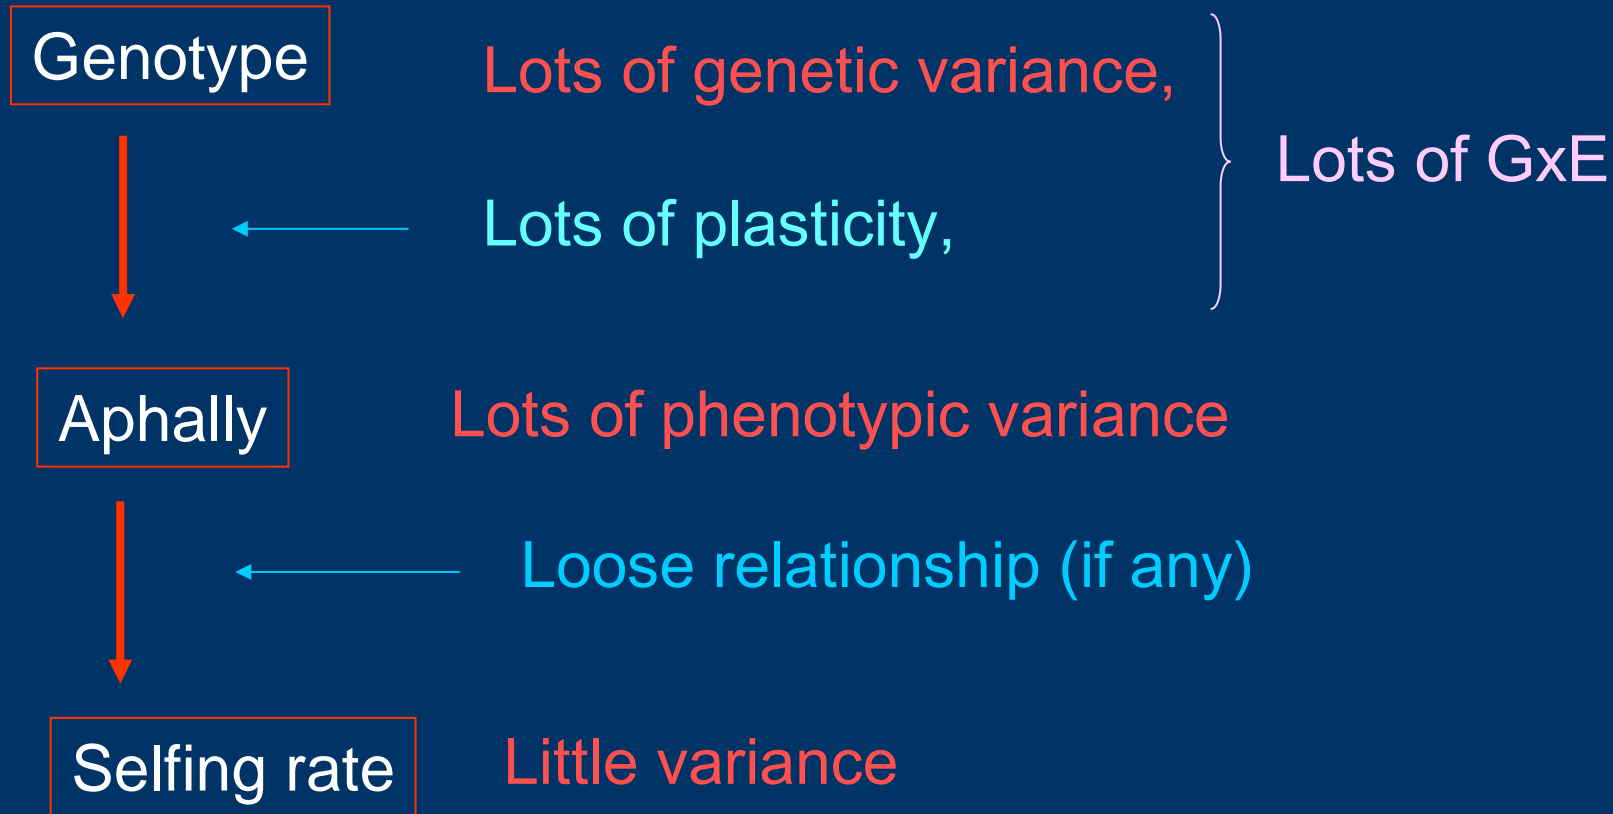

Many populations are obligate selfers (100% A implies $s=1$)

All pops $0.8 < s < 1$

No correlation with % A

Aphally in Bulinus truncatus

Selfing may have evolved first (e.g. through behavioral acceptance of allosperm) then driven the evolution of aphally rather than the reverse !

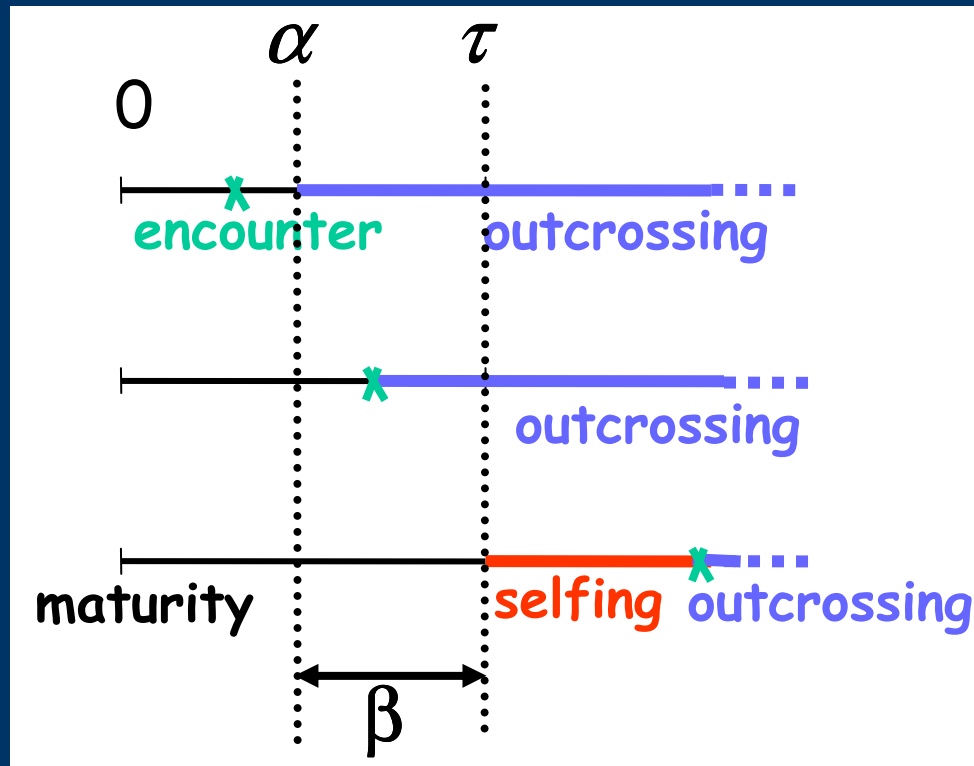

Phylla acuta

- Preferential outcrosser
 $s=0.1$
- Large depression
 $\delta = 0.9$
- No sexual dimorphism

- Hypothesis : uses selfing only as a last chance of reproducing when there are no mates... = reproductive assurance

The waiting time model

abundant mates:
optimal age at first
reproduction α

no (or rare) mates
waiting time β
before selfing

$$\tau = \alpha + \beta$$

baseline time

additional delay to limit selfing

Theoretical Results : optimal waiting times

α baseline time

β additional delay when mates are absent

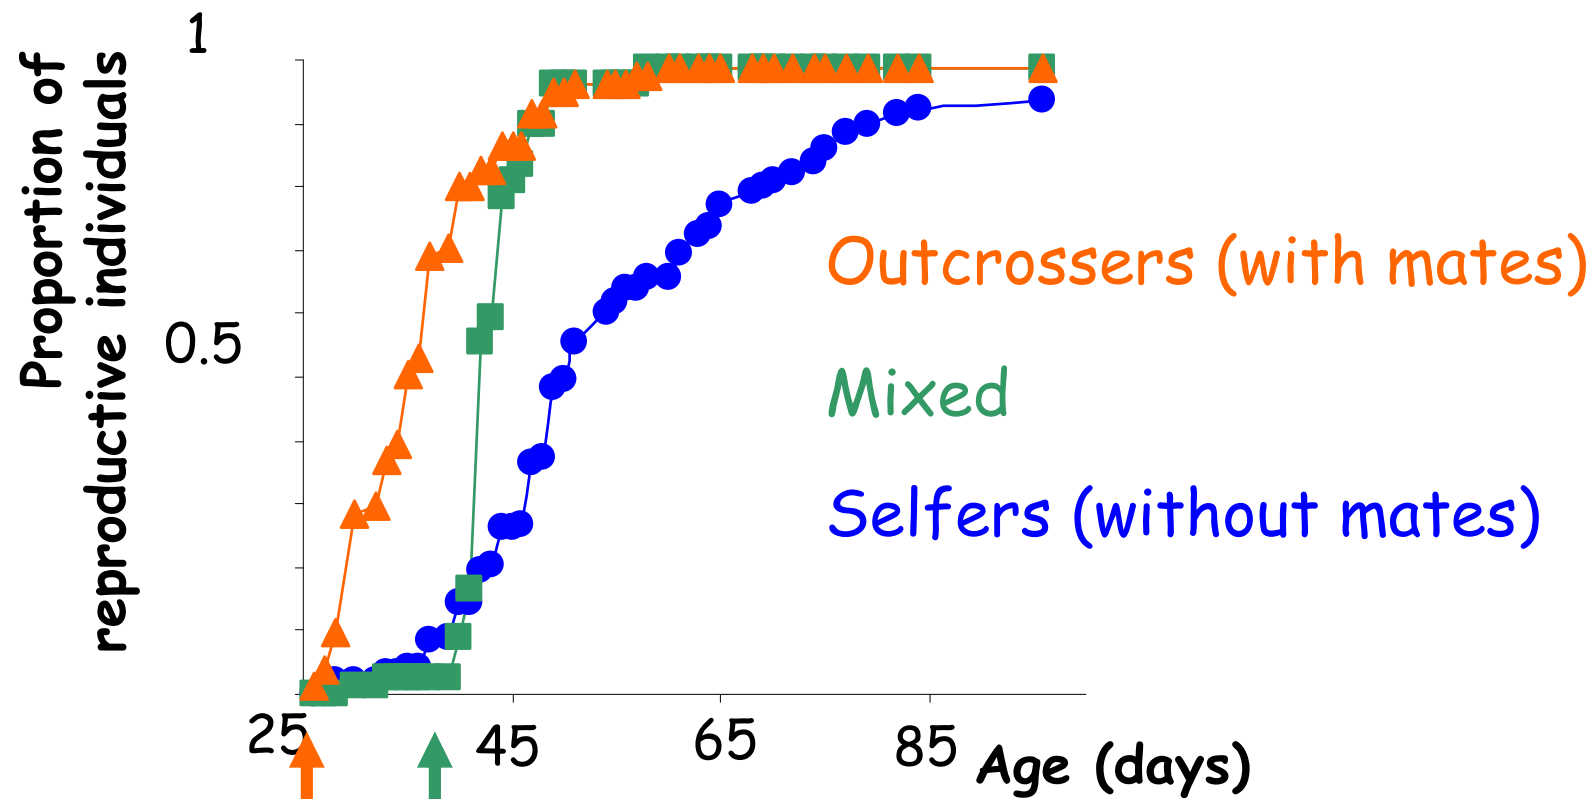

$$(1/m) - (1/k)$$

$$\frac{e}{m(m+e)} \frac{(2\delta - 1)}{2(1 - \delta)}$$

 with mortality m
 with
reallocation
efficiency k
(reallocation from
early to late
reproduction)

 with mortality m
 with encounter rate e
 with inbreeding
depression δ

Data

$\beta = 2$ weeks

Delayed benefits of waiting behavior in selfers

Selfers reproduce later but grow bigger and survive longer

Comparison between model and data, heritability

Survival CMR 0.009 d^{-1}
Senescence $\gamma = 4.15$
Sexual maturity $a = 21 \text{ d}$
Reallocation (fec): $k = 0.07 \text{ d}^{-1}$
Inbreeding depression : 0.9
Encounter rate : ? $0.1-0.9 \text{ d}^{-1}$

prediction

observation

Delay 13.1-18.2 d 17.2 d

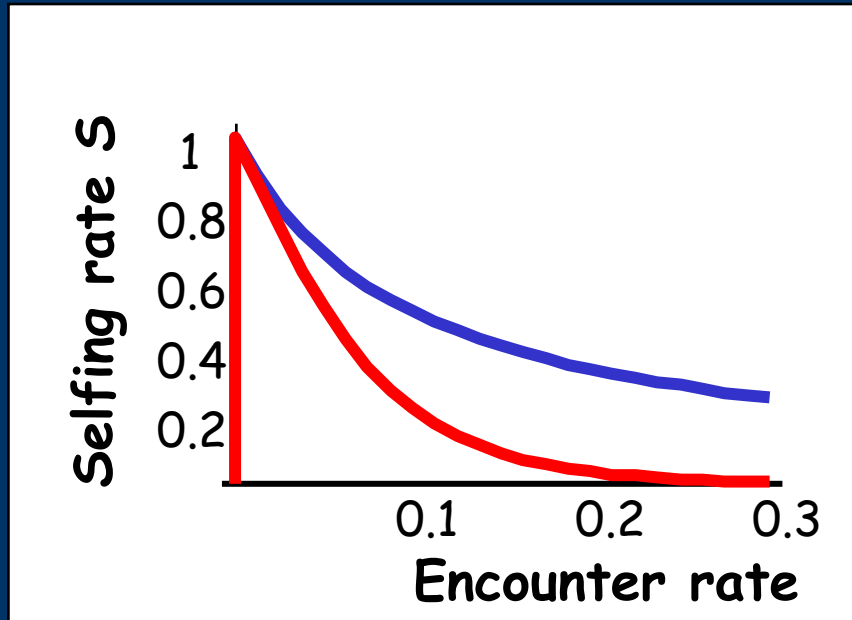

Size 9.3-9.6mm 9.55 mm

Treatment	family	h^2
self	$p < 0.001$	0.41+
outcr	NS	(0)

The waiting time (β) is genetically variable

IT CAN EVOLVE

The waiting behavior keeps selfing rates low

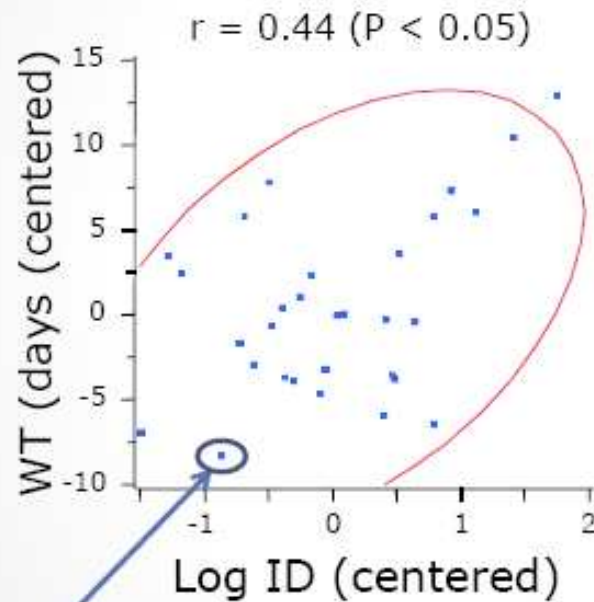

snails with $\beta=0$

snails with optimal β

The waiting behaviour reduces the realized selfing rate except at very low population densities.
Empirically, we usually find $s < 0.2$ (4 populations)

Longer waiting times evolve in populations where selfing is more costly

Variation in WT and ID among populations in *Physa acuta*

1 population (40 isolated + 40 nonisolated individuals)

- different evolutionary optima of WT depending on ID

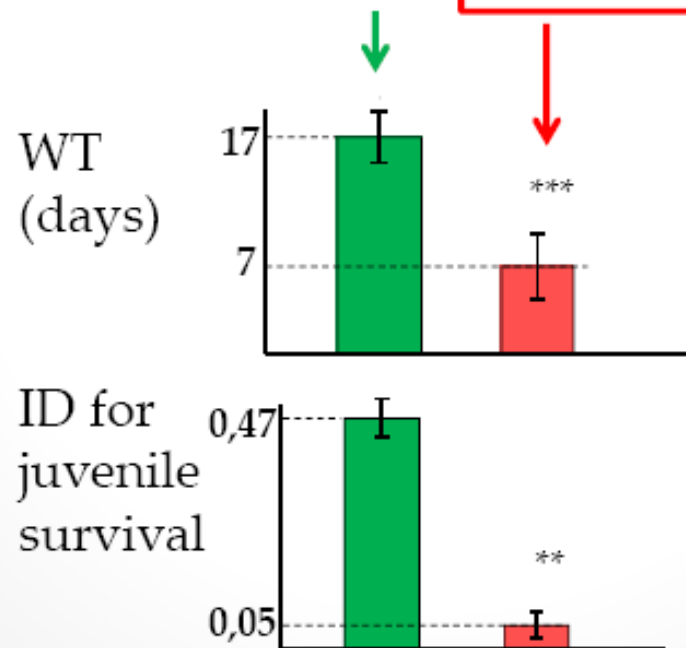

Waiting times rapidly evolve when mates become less available

Coevolution of ID and WT under reduced mating opportunity

- Experimental evolution lines (ca. 20 generations)

C = control lines, many mates available at all times

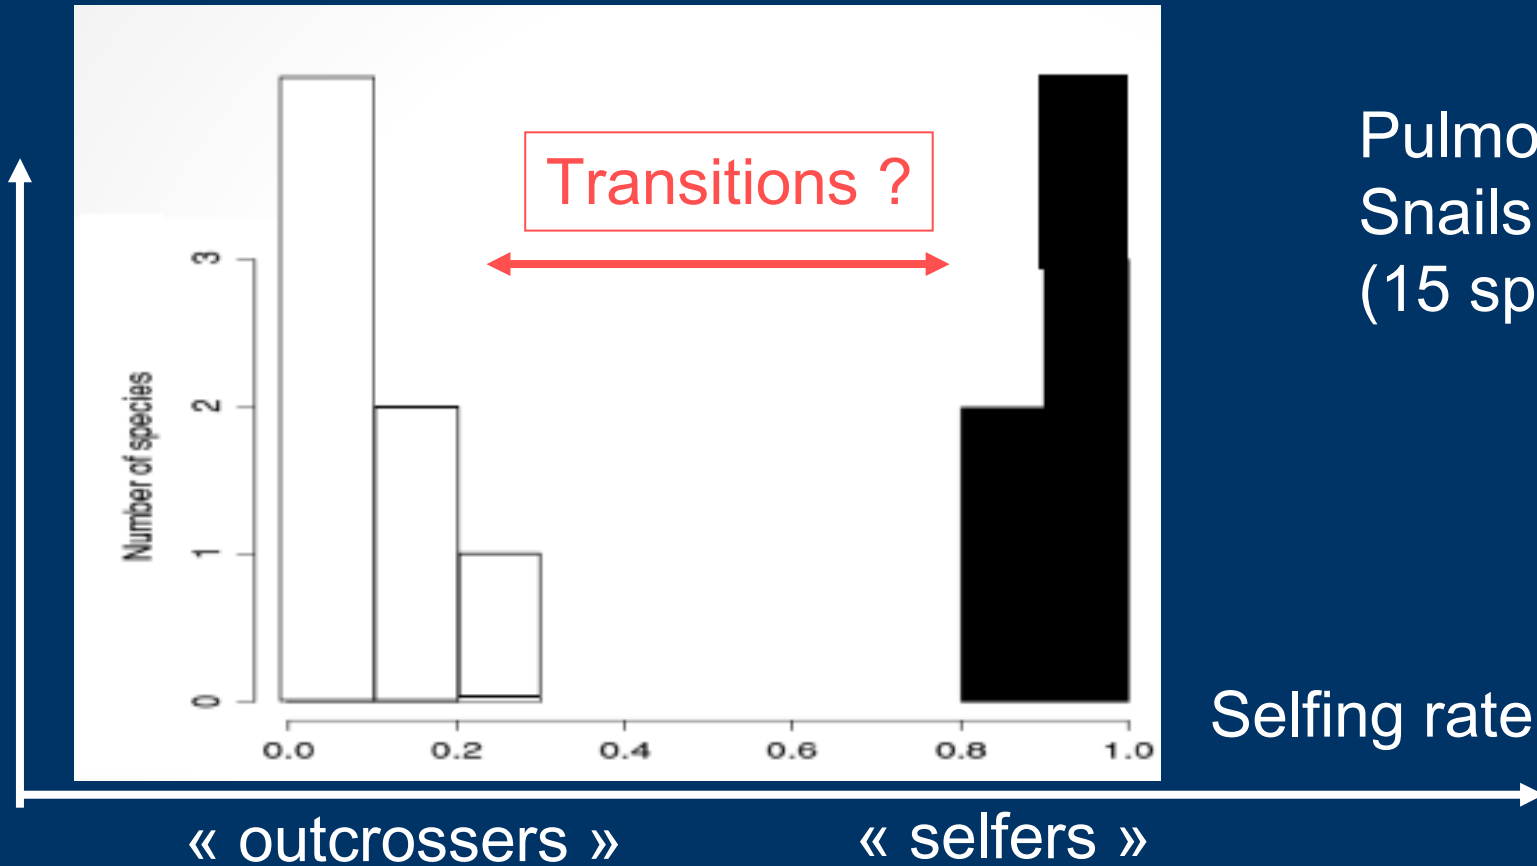

S = constrained lines, 0 or 1 mate, in alternation every other generation

The beginning of a transition towards a highly selfing strategy ?

Evolution of mating system between two stable states ?

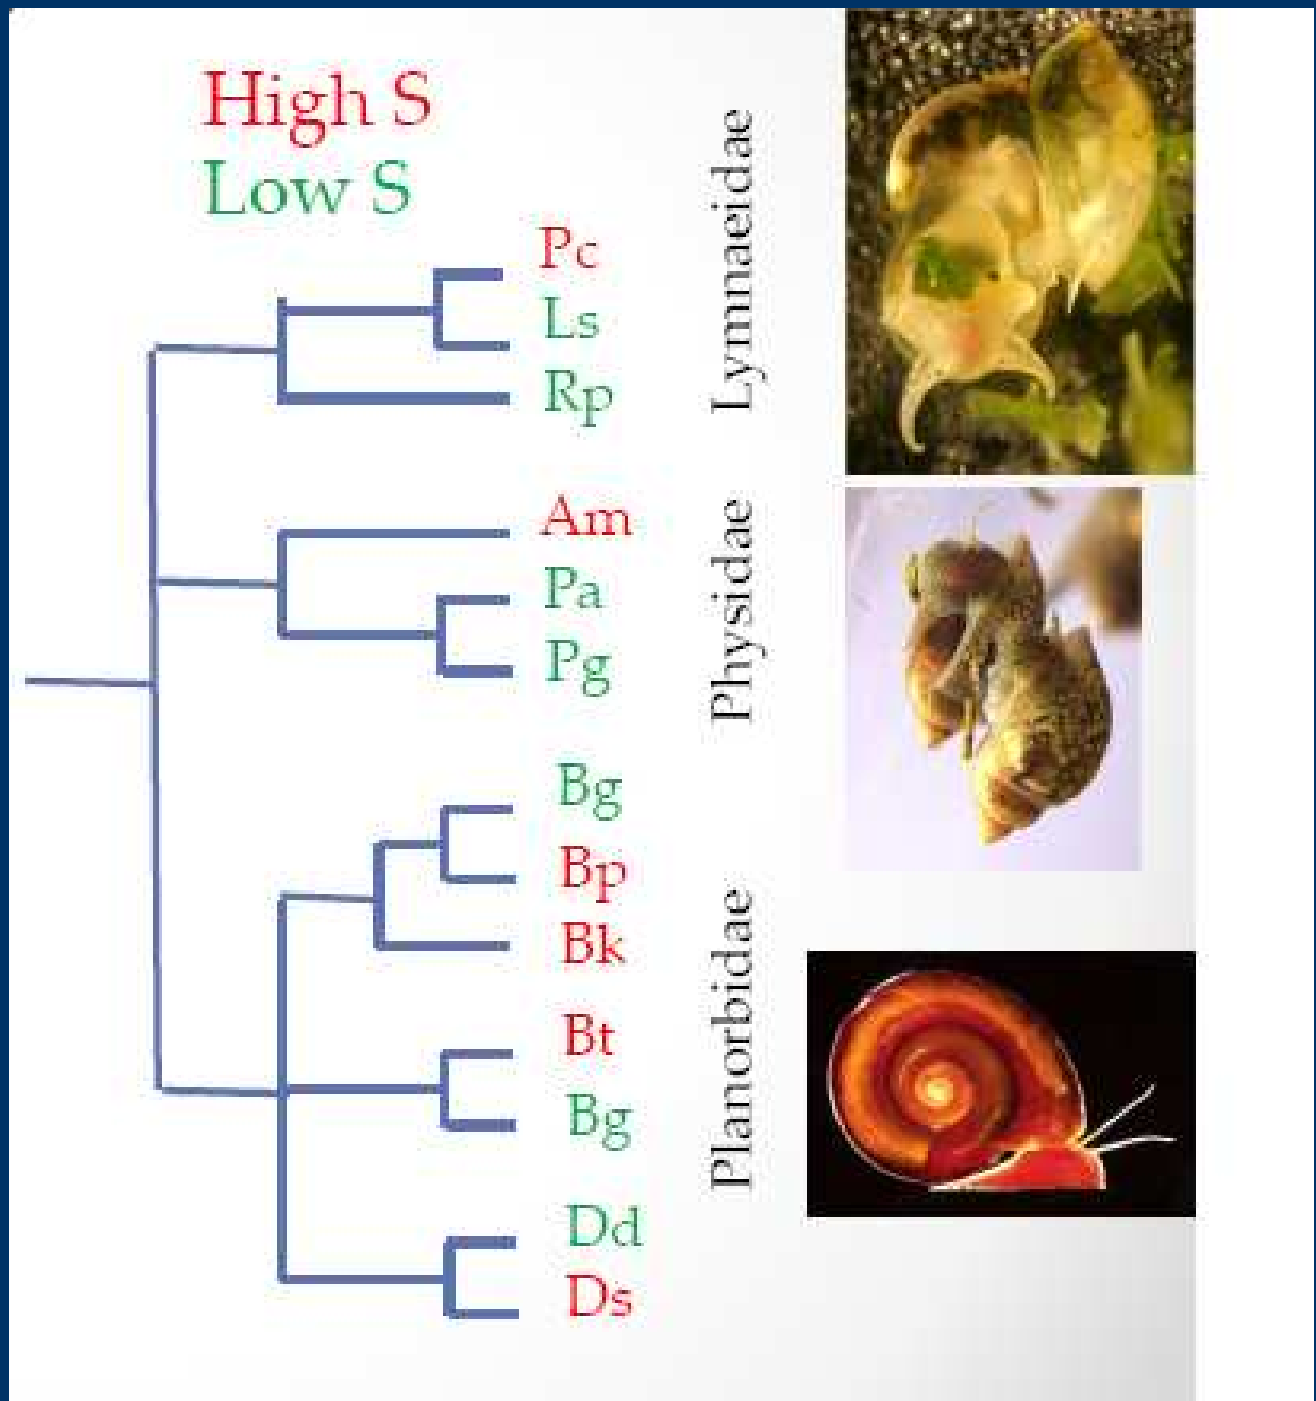

Number of species

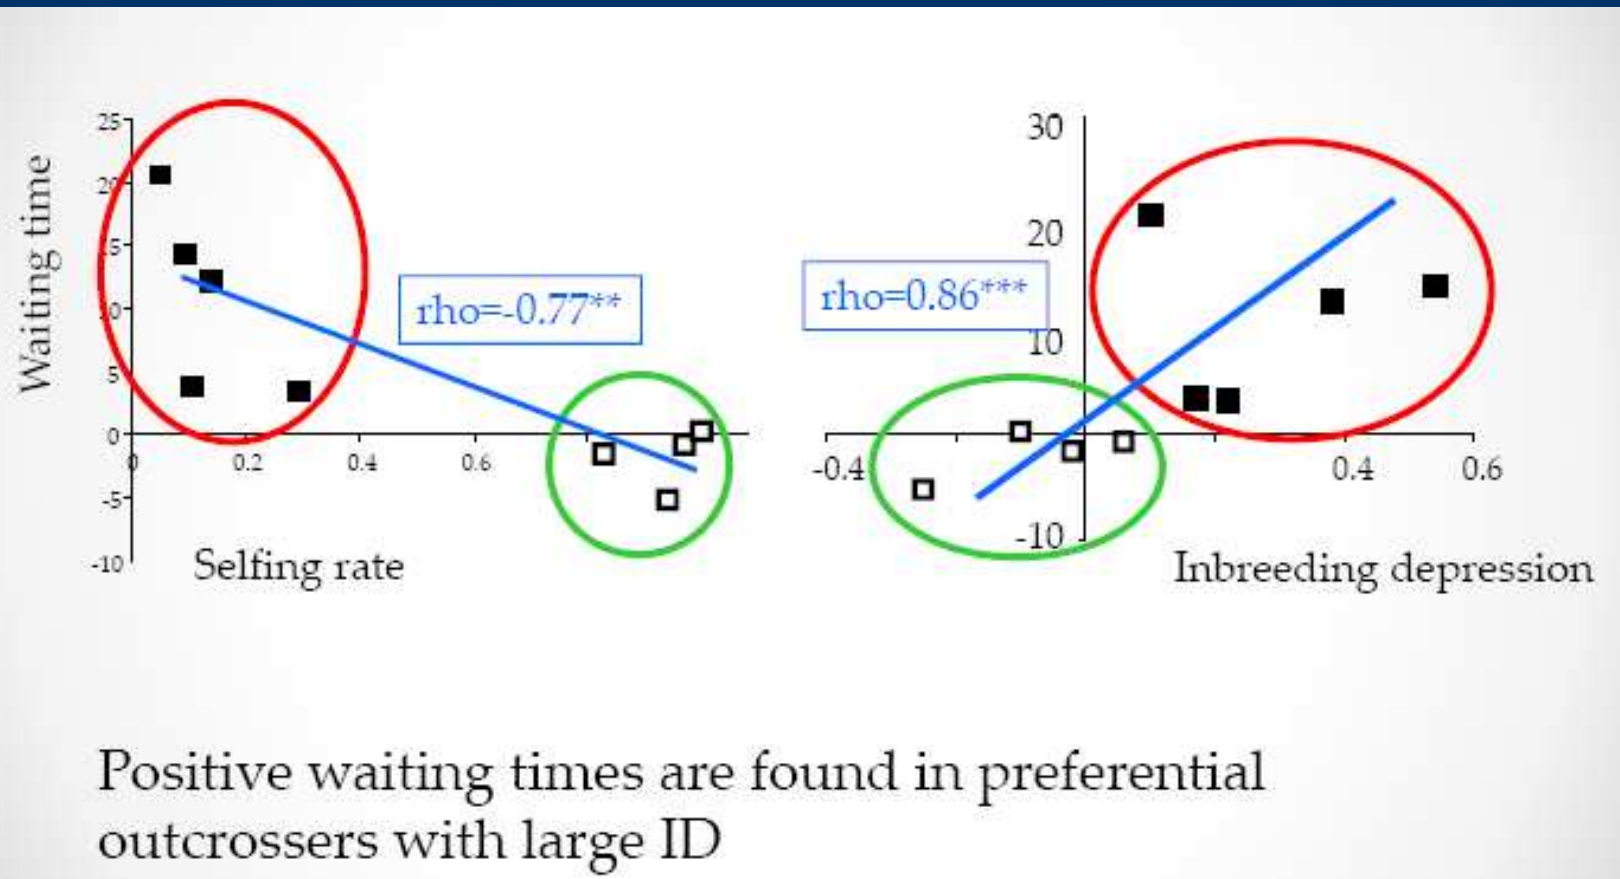

Pulmonate Snails
(15 species)

Evolutionary transitions have occurred in the pulmonate snails

Inbreeding depression and waiting time coevolve with selfing rates

Conclusions

- Hermaphroditism does not mean uniformity : hermaphroditic species contain a diversity of reproductive types, discontinuous (aphallics/euphallics) or continuous (long/short waiting times)
 - these types are (partially) genetically determined and influence the opportunity for self-fertilization
 - This variation allows EVOLUTION of mating systems ; this evolution provides a spectacular illustration of Darwinian principles and models
-
